## Deterministic vs. Randomized Algorithms

The common paradigm in algorithm design is that of deterministic algorithm.

- For a deterministic algorithm the input completely determines the sequence of computations performed by the algorithm.
- The behavior of random algorithms is determined not only on the input but also on several random choices.
- The same randomized algorithm, given the same input multiple times, may perform different computations in each invocation.
- The running time of a randomized algorithm on a given input is a random variable.

#### Deterministic vs. Random Algorithms

## Deterministic vs. Random Algorithm Design

- for deterministic algorithms, good behavior means that time requirements are polynomial in the size of the input;
- for random algorithms we need proof that it is highly likely that the behavior of the algorithm will be good on any input.

## Probabilistic Analysis of Algorithms

- probabilistic Analysis of algorithms is an entirely distinct pursuit;
- random inputs having a given probability distributions are applied;
- goal is to show that the algorithm requires polynomial time on most inputs;

#### Las Vegas vs. Monte Carlo

- A Las Vegas algorithm provides a solution with a probability larger than <sup>1</sup>/<sub>2</sub> and never gives an incorrect solution
- A Monte Carlo algorithm applies in situations when the algorithm makes a decision or a classification and provides a yes/no answer; if the answer is yes, then it confirms it with the probability larger than <sup>1</sup>/<sub>2</sub>, but if the answer is no, the algorithm will never give a definite result.
   The failure of the algorithm to return yes in a long series of trials gives evidence that the answer is no.

#### Example

Let A be an array on n components, where  $n \ge 2$ ; suppose that half of the components of A are 1<sup>s</sup> and the other half are 0<sup>s</sup>. Find an 1 in the array. Consider the algorithms

LV(A,n) begin repeat randomly select one out of *n* elements; until 1 is found end  $\begin{array}{l} \mathsf{MC}(\mathsf{A},\mathsf{n},\mathsf{k}) \\ \mathsf{begin} \\ i = 1; \\ \mathsf{repeat} \\ \mathsf{randomly select one out of } n \ \mathsf{elements}; \\ i = i+1; \\ \mathsf{until} \ i = = k \ \mathsf{or an 1} \ \mathsf{is found}; \\ \mathsf{end} \end{array}$ 

## The Las Vegas Algorithm

```
LV(A,n)
begin
repeat
randomly select one out of n elements;
until an 1 is found;
end
```

- the algorithm succeeds with probability 1;
- the algorithm always outputs the correct answer;
- the running time is a random variable and arbitrarily large but the expected running time is finite.

#### The Monte Carlo Algorithm

MC(A,n,k)
begin
 i = 1;
 repeat
 randomly select one out of n elements;
 i = i + 1;
 until i == k or an 1 is found;
end
 no guarantee of success;

(日) (圖) (E) (E) (E)

run time is fixed.

#### The Relationship between LV and MC

- a LV algorithm can be converted into a MC algorithm by having it output an arbitrary (possibly erroneous) output if it fails to complete under a specified time;
- a MC can be converted in a LV algorithm if there exists an efficient checking the correctness of the answer by repeatedly running the MC until it produces a correct answer.

## **Comparing Binary Strings**

Let  $a = a_0 a_1 \cdots a_{n-1}$  and  $b = b_0 b_1 \cdots b_{n-1}$  be two binary strings, where a is the binary representation of some natural number t.

A Monte Carlo algorithm:

- Alice choses a uniformly random random prime  $p, 2 \le p \le T$ , where  $t \le T$ . The fingerprint of a is  $F_p(a) = a \mod p$ .
- Alice sends  $F_p(a)$  and p to Bob.
- Bob computes F<sub>p</sub>(b). If Bob sees F<sub>a</sub>(p) = F<sub>b</sub>(p), then the algorithm outputs TRUE; otherwise, the algorithm outputs FALSE.

There are no false negatives, since a = b implies  $F_p(a) = F_p(b)$ .

- If  $a \neq b$ , we may still have  $F_p(a) = F_p(b)$ , which is a false positive.
- We claim that the probability of an error is small.

#### ALGORITHM OUTPUT

#### Let

$$prime(x) = |\{p \mid p \text{ is prime and } p \leq x\}|.$$

#### Theorem

A non-zero n-bit integer has at most n distinct prime divisors.

**Proof:** Each prime divisor is at least 2 and the integer is not larger than  $2^n - 1$ . By the unique factorization theorem, there are no more than *n* prime divisors.

Since |a - b| is a non-zero *n*-bit integer, there are at most *n* prime numbers that divide |a - b|. Therefore, the probability of an error is not larger than  $\frac{n}{\text{prime}(\tau)}$ . The prime number theorem states that prime(x) is close to  $\frac{x}{\ln x}$  as  $x \to \infty$ . Thus, the probability of error is less or equal to  $n\frac{\ln T}{T}$ . To limit error choose  $T = cn \ln n$ . In this case

$$P(\text{error}) \leq n \frac{\ln(cn \ln n)}{cn \ln n} = \frac{1}{c} \left( 1 + \frac{\ln(cn \ln n)}{\ln n} \right)$$

Since  $\frac{\ln(cn\ln n)}{\ln n} = o(1)$  we have

$$P(\text{error}) = \frac{1}{c} + o(1).$$

Thus, with c large enough P(error) can be made as small as desired.

.

#### Pattern Matching Problem

Problem: Given two input strings X = x<sub>0</sub>x<sub>1</sub> ··· x<sub>n-1</sub> and Y = y<sub>0</sub>y<sub>1</sub> ··· y<sub>m-1</sub>, is Y a contiguous substring of X?
Equivalent formulation: Is there a j, 1 ≤ j ≤ n - m such that for X(j, m) = x<sub>j</sub>x<sub>j+1</sub> ··· x<sub>j+m-1</sub>, X(j, m) = Y?

### The Algorithm

- regard X and Y as binary integers;
- choose a random prime p, where  $2 \leq p \leq T$ ;
- compute the fingerprints  $F_p(Y)$  and  $F_p(X(j,m))$  for  $0 \leq j \leq n-m$ ;
- if there is some j such that  $F_p(Y) = F_p(X(j, m))$ , then output MATCH, otherwise output NO MATCH.

- there are no false negatives, but there may be false positives, when strings do not match, but the algorithm returns MATCH;
- if  $X(j,m) \neq Y$  for  $0 \leq j \leq n-m$ , then, by the union bound,

$$P(\text{error}) \leqslant n \frac{\text{prime}(m)}{\text{prime}(T)}$$

## A Tighter Bound

- if  $F_p(X(j,m)) = F_p(Y)$ , then p divides |X(j) Y|;
- if there is an error, then p divides the product  $\prod_{j=0}^{n-m} |X(j,m) Y|$ .
- since |X(j,m) − Y| is an m bit number and we multiply these, ∏<sub>j=0</sub><sup>n-m</sup> |X(j,m) − Y| is a most an mn-bit integer;

   therefore.

$$P(\operatorname{error}) \leqslant rac{\operatorname{prime}(mn)}{\operatorname{prime}(T)}.$$

• if 
$$T = cmn$$
 we have  $P(error) \leq \frac{prime(mn)}{prime(cmn)} = \frac{1}{c} \left(1 + \frac{\ln c}{\ln mn}\right)$ 

< □ > < @ > < 클 > < 클 > · 클 · 의익은 21/91

#### Example

The size of a human chromosome ranges from  $50\cdot 10^6$  to  $250\cdot 10^6$  base pairs.

If we are looking for a string of length  $m = 2^8$  in a DNA string of length  $n = 2^{27}$  (within the ballpark of chromosome length), then by choosing  $T = 2^{64}$  (so p is a 64-bit integer) gives  $c = \frac{T}{mn} = \frac{2^{64}}{2^{35}} = 2^{29};$  $P(\text{error}) \leqslant \frac{1}{2^{29}} (1 + \frac{29}{35})$ , which is minuscule!

## Polynomial Identity Testing

A polynomial  $P(x_1, ..., x_n)$  over a field  $\mathbb{F}$  can be written as a sum of monomials of the form  $cx_1^{k_1} \cdots x_n^{k_n}$ . For example, for  $p = (x + y)(2x + z^2)$  we can write

$$p(x, y, z) = 2x^2 + 2xy + xz^2 + yz^2.$$

23/91

## Two Problems on Polynomials

- The "Evaluates to Zero Everywhere" (EZE) problem: Given a polynomial D(x<sub>1</sub>,...,x<sub>n</sub>) over F, decide whether, for every choice of y<sub>1</sub>,..., y<sub>n</sub> in F the value of D(y<sub>1</sub>,..., y<sub>n</sub>) is 0.
- The Polynomial Identity Testing (PIT) Problem: Given a polynomial D(x<sub>1</sub>,...,x<sub>n</sub>), we can write it as a sum of monomials. If, upon expanding p to a sum of monomials, each coefficient is 0, then we say that p is the zero polynomial, or that it is identically zero.

- if p is identically zero then it evaluates to zero everywhere;
  if F is R or C the converse is true:
- if  $\mathbb{F}$  is some finite field the converse is false; for example if  $p(x) = x^2 + x$  is a polynomial over GF(2), then p is not identically zero, but p(x) = 0 for  $x \in \{0, 1\}$ .

The brute force approach is unfeasible. If we explicitly expand p and  $\partial(p) = d$ , then there could by  $\binom{n+d}{d}$  monomials (which is exponential in d).

## The Degree of a Multivariate Polynomial

A monomial is an expression of the form  $\mu = ax_1^{b_1} \cdots x_n^{b_n}$  where  $a \in \mathbb{F}$  and  $b_1, \cdots, b_n \in \mathbb{N}$ . The degree of  $\mu$  is  $\sum_{i=1}^n b_i$ . The degree of a polynomial is the largest degree of any of its monomials.

#### **Polynomial Representations**

Polynomials can be represented explicitly, as sums of monomials.
 Other forms are possible. For example, V(x<sub>1</sub>,..., x<sub>n</sub>) defined by

$$V(x_1,...,x_n) = \begin{vmatrix} 1 & 1 & \cdots & 1 \\ x_1 & x_2 & \cdots & x_n \\ \vdots & \vdots & \cdots & \vdots \\ x_1^{n-1} & x_2^{n-1} & \cdots & x_n^{n-1} \end{vmatrix} = \prod_{i < j} (x_i - x_j)$$

イロト イロト イヨト イヨト 三日

28/91

is the Vandermonde polynomial of degree  $\frac{n(n-1)}{2}$ .

Given a polynomial  $D(x_1, \ldots, x_n)$  of *n* variables and of degree *d* is *D* identical to the 0 polynomial?

Basic assumption: there is an efficient way of computing the values of *D*. Algorithm:

Let  $S \subseteq \mathbb{R}$  be a finite set. Pick at random uniformly and independently  $r_1, \ldots, r_n$  from S. If  $D(r_1, \ldots, r_n) = 0$  return YES; otherwise, return NO.

If  $D \equiv 0$ , the algorithm returns YES with probability 1, so the possible error is one-sided.

#### Theorem

The Inequality of Schwartz-Zippel If D is a polynomial of degree d and  $D \neq 0$ , then

$$P(D(r_1,\ldots,r_n)=0)\leqslant \frac{d}{|S|}$$

(日) (圖) (E) (E) (E)

30/91

#### Proof

The argument is by induction on n.

The base step n = 1 follows from the fact that there are at most d roots, so  $P(D(r_1) = 0) \leq \frac{d}{|S|}$ . The inductive step: Note that D can be written as

$$D(x_1,\ldots,x_n)=\sum_{i=1}^k x_1^i Q_i(x_2,\ldots,x_n),$$

where k is the largest power of  $x_1$  in a monomial of D. By our choice of k the polynomial  $Q_k(x_2, \ldots, x_n)$  is not identically 0 and its degree is no larger than d - k.

## Proof (cont'd)

By the inductive hypothesis

$$P(Q_k(x_2,\ldots,x_n)=0)\leqslant \frac{d-k}{|S|}.$$

Let K be the event " $Q_k(x_2,\ldots,x_n) = 0$ ".

Let us now randomly choose the values of  $y_2, \ldots, y_n$  and assume that the event K did not occur. Define  $\Delta(x_1)$  to be the univariate polynomial

$$\Delta(x_1) = \sum_{i=1}^k x_1^i Q_i(y_2,\ldots,y_n),$$

Since K did not occur, the degree of  $\Delta$  is k. Thus,

$$P(\Delta(y_1) = 0 | \bar{K}) \leq \frac{k}{|S|}.$$

Let L be the event "
$$\Delta(y_1) = 0$$
", clearly equivalent to  $D(y_1, y_2, \dots, y_n) = 0$ .  
We have

$$P(L) = P(L \cap K) + P(L|\bar{K})P(\bar{K})$$
  
$$\leq P(K) + P(L|\bar{K})P(\bar{K})$$
  
$$\leq \frac{k}{|S|} + \frac{d-k}{|S|} = \frac{d}{|S|}.$$

#### Recall

#### Markov's Inequality:

If X is a non-negative random variable having the expected value E[X], then  $P(X \ge a) \le \frac{E[X]}{a}$ .

**Proof:** (for the discrete case). Let  $X : \begin{pmatrix} x_1 & x_2 & \cdots & x_n \\ p_1 & p_2 & \cdots & p_n \end{pmatrix}$ , where  $x_1 > x_2 > \cdots > x_n$ ,  $p_i \ge 0$  for  $1 \le i \le n$  and  $\sum_{i=1}^n p_i = 1$ . If  $x_i \ge a > x_{i+1}$ , we have

$$P(X \ge a) = P((X = x_1) \cup (X = x_2) \cup \cdots \cup (X = x_i)) = p_1 + \cdots + p_i.$$

On other hand,

$$E[X] = x_1p_1 + \dots + x_ip_i + x_{i+1}p_{i+1} + \dots + x_np_n$$
  

$$\geqslant x_1p_1 + \dots + x_ip_i$$
  

$$\geqslant a(p_1 + \dots + p_i) = aP(X \ge a).$$

#### Maximal Cut

Given a graph  $\mathcal{G} = (V, E)$  find a partition  $\{S, T\}$  of the set V of vertices (called a cut) such that the number of edges between S and T is maximal. The set of edges that join a vertex in S with a vertex in T is denoted by E(S, T) and the size of the cut is |E(S, T)|.

#### Theorem

In any graph  $\mathcal{G} = (V, E)$  there exists a cut with at least half of the edges crossing it.

< □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □ > < □
#### Proof

Let S be a random subset of V. A vertex belongs to S with probability 0.5. The indicator of an edge e is the random variable  $X_e$ , where

$$X_e = egin{cases} 1 & ext{if } e \in E(S,T), \ 0 & ext{otherwise} \end{cases}$$

For X = |E(S, T)| we have  $X = \sum_{e \in E} X_e$  and

$$E[X_e] = P(e \in E(S,T)) \cdot 1 + P(e \notin E(S,T)) \cdot 0 = \frac{1}{2}$$

because the probability that an end of *e* is in *S* and the other is not is  $\frac{1}{2}$ . Therefore  $E[X] = \sum_{e \in E} E[X_e] = \frac{|E|}{2}$ . There exits an event where *X* takes a value at least E[X], so there is a cut with at least half the edges.

### The Random Assignment of Vertices

Suppose that in order to build a cut (S, T) we assign vertices at random to S or T.

Let Y = |E| - X be the number of edges that to not cross from S to T. We have  $Y \ge 0$  and  $E[Y] = |E| - E[X] = \frac{|E|}{2}$ . By Markov's inequality

$$P(Y \geqslant aE[Y]) = P(Y \geqslant \frac{a|E|}{2}) \leqslant \frac{1}{a}$$

For a = 1.5 we have

$$P(Y \ge \frac{3}{4}|E|) \le \frac{2}{3}$$
, or  $P(Y < \frac{3}{4}|E|) > \frac{1}{3}$ .

Therefore,  $P(X > \frac{1}{4}|E|) \ge \frac{1}{3}$ , which shows that a random cut will have at least a quarter of the edges with a probability of at least  $\frac{1}{3}$ .

### The 3-SAT Problem

The 3-SAT problem starts with a formula in conjunctive normal form

$$\varphi = C_1 \wedge C_2 \wedge \cdots \wedge C_m,$$

where each clause  $C_i$  is disjunction of three distinct literals of the form  $C_i = \ell_j \lor \ell_k \lor \ell_h$ , and seeks to determine if there exists a truth assignment that satisfies all  $\varphi$ .

Here  $\ell$  is either a propositional variable  $x_i$  or its negation  $\bar{x}_i$ .

#### Example

Consider the clause  $C = x_1 \lor \bar{x}_2 \lor \bar{x}_3$  and the list of truth assignments on the set of variables of this clause:

One out of every eight truth assignments fails to satisfy the clause!

#### Example

Let  $\varphi$  be the formula

$$(\bar{x}_1 \lor \bar{x}_2 \lor x_3) \land (x_1 \lor \bar{x}_2 \lor \bar{x}_3) \land (x_1 \lor x_2 \lor x_3).$$

The truth assignment v on  $\{x_1, x_2, x_3\}$  given by  $v(x_1) = 1$ , and  $v(x_2) = v(x_3) = 0$  satisfies  $\varphi$ .

# Instead of solving SAT let's seek a truth assignment that satisfies the maximum number of clauses.

#### Theorem

For every formula  $\varphi$  there exists a truth assignment that satisfies  $\frac{7m}{8}$  clauses.

#### Proof

Choose randomly a truth assignment  $v : \{x_1, \ldots, x_n\} \longrightarrow \{\mathbf{T}, \mathbf{F}\}$ . Define

$$Y_i = egin{cases} 1 & ext{if } C_i ext{ is satisfied}, \ 0 & ext{otherwise}. \end{cases}$$

The number of satisfied clauses is  $Y = \sum_{i=1}^{m} Y_i$ . Among 8 truth assignments to the variables of  $C_i$  only one fails to satisfy  $C_i$ . Thus, we have  $E[Y_i] = P(C_i \text{ is satisfied}) = \frac{7}{8}$ , so  $E[Y] = \sum_{i=1}^{m} E[Y_i] = \frac{7m}{8}$ . Since there exists an event in the probability space such that Y is greater than E[Y], there exists an assignment that satisfies  $\frac{7}{8}$  of the clauses.

### How to Get a Good Truth Assignment

Let Z = m - Y be the number of unsatisfied clauses,  $Z \ge 0$ . We have

$$E[Z] = m - E[Y] = \frac{m}{8}.$$

By Markov's Inequality,

$$P(Z \ge aE[Z]) = P(Z \ge \frac{am}{8}) \le \frac{1}{a},$$

so for a = 2,  $P(Z \ge m/4) \le 1/2$ , which implies

$$P\left(Y > \frac{3m}{4}\right) > \frac{1}{2}$$

Thus, a randomly chosen assignment satisfies at least three quarters of clauses with at least 0.5 probability!

44/91

Let  $\Gamma_{n,p}$  the distribution of random undirected graphs with *n* vertices such that an edge exists with probability *p*. We say that  $G \sim \Gamma_{n,p}$  is G = (V, E) belongs to this distribution.

- a graph in  $\Gamma_{n,p}$  with a given set of *m* edges has the probability  $p^m(1-p)^{\binom{n}{2}-m}$ ;
- a graph in Γ<sub>n,p</sub> can be generated by considering each of the <sup>(n)</sup><sub>2</sub> edges and then, independently add each edge to the graph with probability p; the expected number of edges is <sup>(n)</sup><sub>2</sub>p and each vertex has expected degree (n − 1)p.

Studying  $\Gamma_{n,p}$  yields interesting a powerful results. For example, for  $G \sim \Gamma_{n,p}$  does G contain a clique having four vertices?

Define for every set C of 4 vertices in G, an indicator variable  $I_C$  by

$$I_C = egin{cases} 1 & ext{if } C ext{is a clique} \ 0 & ext{otherwise.} \end{cases}$$

There are  $\binom{n}{4}$  sets *C*, so there is this number of indicator variables. If  $X_n$  is the number of 4-cliques in a graph with *n* vertices,  $X_n = \sum \{I_C | C \subseteq V, |C| = 4\}$ . There are six edges in a 4-clique, and each is chosen independently, hence

$$E[I_C]=P(I_C=1)=p^6,$$

because each of the six edges are chosen independently. This implies

$$E[X_n] = \binom{n}{4} p^6 = \Theta(n^4 p^6).$$

<ロト < 部 > < 言 > < 言 > こ 2 の Q (C) 47/91 Note that P(X<sub>n</sub> > 0) = P(X<sub>n</sub> ≥ 1) Thus, if lim<sub>n→∞</sub> n<sup>4</sup>p<sup>6</sup> = 0 (written as p ≪ n<sup>-2/3</sup>), then lim<sub>n→∞</sub> P(X<sub>n</sub> > 0) = 0.
 We claim that if p ≫ n<sup>-2/3</sup>, then lim<sub>n→∞</sub> P(X<sub>n</sub> > 0) = 1.

#### Recall

- For a random variable X, the variance is var(X) is  $E[(X E[X])^2]$ . We also have  $var(X) = E[X^2] - (E[X])^2$ .
- For any two random variables X and Y, the covariance cov(X, Y) is E[XY] - E[X]E[Y]. If X and Y are independent, then cov(X, Y) = 0.
- Chebyshevs Inequality: P(|X E[X]| ≥ a) ≤ var(X)/a<sup>2</sup>.
   Proof: Let Y = (X E[X])2. Y is a non-negative random variable, so by applying Markov Inequality,

$$P(|X - E[X]| \ge a) = P(Y \ge a^2) \le \frac{E[Y]}{a^2} = \frac{var(X)}{a^2}$$

# Proof that $p \gg n^{-\frac{2}{3}}$ , implies $\lim_{n\to\infty} P(X_n > 0) = 1$

Note that  $X_n = 0$  implies  $|X_n - E[X_n]| = |E[X_n]| \ge E[X_n]$ . Therefore,

$$P(X_n = 0) \leq P(|X_n - E[X_n]| \geq E[X_n]) \leq \frac{var(X_n)}{E[X_n]^2} = \frac{E[X_n^2] - E[X_n]^2}{E[X_n]^2}.$$

We claim that  $E[X_n^2] - E[X_n]^2$  is small compared to  $E[X_n]^2$ .

# Proof (cont'd)

$$var(X_n) = E[X_n^2] - E[X_n]^2 = E\left[\left(\sum_C I_C\right)^2\right] - E\left[\sum_C I_C\right]^2$$
$$= E\left[\sum_C I_C^2 - \sum_{C \neq D} I_C I_D\right] - \left(\sum_C E[I_C]\right)^2$$
$$= \sum_C E[I_C^2] - \sum_{C \neq D} E[I_C I_D] - \sum_C E[I_C]^2 + \sum_{C \neq D} E[I_C]E[I_D]$$
$$= \sum_C var(I_C) + \sum_{C,D} cov(I_C, I_D).$$

# Evaluation of $cov(I_C, I_D)$

Cases to consider:

- if  $|C \cap D| \leq 1$ , no common edges exist, so  $I_C, I_D$  are independent, which implies  $cov(I_C, I_D) = 0$ ;
- if |C ∩ D| = 2, one pair of vertices is shared, so we need only 11 edges to be present; thus,

 $cov(I_C, I_D) = E[I_C I_D] - p^{12} = p^{11} - p^{12} \leq p^{11}$ ; this can happen  $\binom{n}{6}$  times, so the total contribution is less than  $\binom{n}{6}p^{11} = \Theta(n^6p^{11})$ ;

if |C ∩ D| = 3, three pairs of vertices are shared, so three fewer edges are needed; thus, cov(I<sub>C</sub>, I<sub>D</sub>) = E[I<sub>C</sub>I<sub>D</sub>] - p<sup>12</sup> = p<sup>9</sup> - p<sup>12</sup> ≤ p<sup>9</sup>; this may happen (<sup>n</sup><sub>5</sub>) times, so the total contribution to the sum is (<sup>n</sup><sub>5</sub>)p<sup>9</sup> = Θ(n<sup>5</sup>p<sup>9</sup>);

### Evaluation of $cov(I_C, I_D)$ (cont'd)

We have

$$var(I_C) = E[I_C^2] - E[I_C]^2 = p^6 - p^{12} = \Theta(p^6),$$

which implies

$$var(X_n) = \sum_{C} var(I_C) + \sum_{C \neq D} cov(I_C, I_D)$$
  

$$\leqslant \Theta(n^4 p^6) + \Theta(n^6 p^{11}) + \Theta(n^5 p^9)$$
  

$$= \Theta(n^4 p^6) + \Theta(n^6 n^{-\frac{22}{3}}) + \Theta(n^5 n^{-6})$$
  
(taking into account that  $p \gg n^{-\frac{2}{3}}$ )  

$$= \Theta(n^4 p^6)$$

53/91

◆□ → ◆聞 → ◆臣 → ◆臣 → □ 臣

# Evaluation of $cov(I_C, I_D)$ (cont'd)

Finally,

$$\frac{\operatorname{var}(X_n)}{(E[X])^2} = \frac{\Theta(n^4 p^6)}{\Theta(n^4 p^6)^2} = \frac{1}{\Theta(n^4 p^6)},$$
  
so  $\lim_{n \to \infty} \frac{\operatorname{var}(X_n)}{(E[X])^2} = 0$  because  $p \gg n^{-\frac{2}{3}}$ .

Given three matrices  $A \in \mathbb{R}^{m \times p}$ ,  $B \in \mathbb{R}^{p \times n}$  and  $C \in \mathbb{R}^{m \times n}$  determine if AB = C.

Freivalds' Monte Carlo algorithm:

#### begin

```
i = 1;
```

#### repeat

```
choose \mathbf{r} = (r_1, \dots, r_n)' \in \{0, 1\}^n at random;
compute C\mathbf{r} and A(B\mathbf{r});
if C\mathbf{r} \neq A(B\mathbf{r});
return FALSE;
endif;
i = i + 1;
until i = k;
return TRUE
```

#### Theorem

Freivalds' algorithm is correct with a probability at least equal to  $1 - 2^{-k}$ .

**Proof:** We show that if  $AB \neq C$ , then  $P(A(B\mathbf{r}) = C\mathbf{r}) \leq 1/2$ . If  $AB \neq C$ , then  $D = AB - C \neq 0$ . Without loss of generality we may assume that  $d_{11} \neq 0$ . Note that  $A(B\mathbf{r}) = C\mathbf{r}$  is equivalent to  $D\mathbf{r} = \mathbf{0}$  and this implies  $\sum_{j=1}^{n} d_{1j}r_j = 0$ . Since  $d_{11} \neq 0$ , we have  $r_1 = -\frac{\sum_{j=2}^{n} d_{1j}r_j}{d_{11}}$ . This equality holds for at most one of the two choices we have for  $r_1$ , so  $P(AB\mathbf{r} = C\mathbf{r}) \leq 0.5$ . If C = AB the algorithm is always correct; if  $C \neq AB$  the probability of a correct answer is  $1 - 0.5^k$  because the loop is run for k times.

### Finding the nearest pair of points

This is the first probabilistic algorithm by M. Rabin, published in 1976! Problem Statement: given *n* points  $\mathbf{x}_1, \ldots, \mathbf{x}_n$  in the unit square  $[0, 1]^2$  in  $\mathbb{R}^2$  find two points that are the closest with respect to Euclidean distance. To simplify the presentation assume that there is a unique closest pair. If there are several with the same minimum distance the algorithm still works. The problem can clearly be solved in  $O(n^2)$ , but randomness allows a better result!

### Outline of Rabin's Algorithm

Let S be a set of points in  $\mathbb{R}^2$  and let

$$\delta(S) = \min\{d(\mathbf{u}, \mathbf{v}) \mid \mathbf{u}, \mathbf{v} \in S \text{ and } \mathbf{u} \neq \mathbf{v}\}$$

Consider a mesh of squares  $\mathcal{M}$  having the size  $\delta$ .

Key remark: Even if  $\delta(S) \leq \delta$  we cannot be certain that the nearest pair is in the same square of the mash. However, we are sure that at worst the closest pair lies in squares with a common vertex.

#### Lemma

If  $\delta(S) \leq \delta$ , where  $\delta$  is the mesh size, then there exists a mesh point **y** such that the nearest pair lies in a quadruple of squares situated at the north and east of **y**.

S can be partitioned in a union of sets,  $S = S_1 \cup \cdots \cup S_k$  such that each  $S_i$  consists of all the points of S within one square of  $\mathcal{M}$ . Define  $N(\mathcal{M}) = \sum_{i=1}^k \frac{n_i(n_i-1)}{2}$ .

- if we know that the nearest pair is within one of the sets S<sub>i</sub>, then it can be discovered by performing N(M) computations;
- under the previous assumption, the nearest pair will be discovered after N(M) 1 comparisons between the computed distances;
- thus, we are interested in finding a mesh  $\mathcal{M}$  for which  $N(\mathcal{M}) = O(n)$ .

### The effect of increasing the mesh size $\delta$

#### Lemma

Let  $\mathcal{M}$  be a mesh of size  $\delta$ . Construct a mesh  $\mathcal{M}_1$  by choosing a fixed mesh point **y** of  $\mathcal{M}$  as origin and forming a mesh of size  $2\delta$  and lines parallel to those of  $\mathcal{M}$ . Then, for a fixed set S we have

 $N(\mathcal{M}_1) \leqslant 16N(\mathcal{M}) + 24n.$ 

#### Proof

The squares of  $\mathcal{M}_1$  are quadruples of squares of  $\mathcal{M}$  and yield the partition  $S = T_1 \cup \cdots \cup T_q$ . • each  $T_i$  is the union of at most four of the sets  $S_j$ ; • if  $|T_i| = m_i$  and  $T_i = S_{j_1} \cup \cdots \cup S_{j_4}$ , then  $m_i \leq n_{j_1} + \cdots + n_{j_4}$ ; • if  $k_i = \max\{n_{j_1}, \dots, n_{j_4}\}$ , then  $\frac{m_i(m_i - 1)}{2} \leq \frac{4k_i(4k_i - 1)}{2} = \frac{16k_i(k_i - 1)}{2} + 6k_i$ . • since  $k_1, \dots, k_m$  are a subset of  $n_1, \dots, n_k$  and  $\sum n_i \leq 4n$  because

every  $\mathbf{x}_i$  in S is in at most four  $S_j$ s, the conclusion follows.

#### Theorem

There exists a constant  $c_1$  so that for every S, M and  $M_1$  as above, if  $N(M) \leq cn$ , then  $N(M_1) \leq c_1 cn$ .

This holds (with an appropriate  $c_1$ ) for any fixed linear blowup of the mesh size of  $\mathcal{M}$ .

#### Theorem

For any set  $S \subseteq \mathbb{R}^2$ , where |S| = n, there exists a mesh  $\mathcal{M}_0$  so that  $\mathcal{M}_0$  creates a partition  $\{S_1, \ldots, S_k\}$  such that  $n \leq \mathcal{N}(\mathcal{M}_0) \leq c_1 n$ , where  $c_1$  is the previous constant.

### Proof

Choose a pair of perpendicular directions  $\ell_1, \ell_2$  intersecting at **y** such that  $S \cap (\ell_1 \cup \ell_2) = \emptyset$ ;

- form a mesh *M* using *l*<sub>1</sub>, *l*<sub>2</sub> and **y** with a small enough size such that each square contains one point of *S* and no point of *S* is located on the grid lines;
- by successively doubling the mesh size we reach for the first time a mesh M<sub>0</sub> for which n ≤ N(M<sub>0</sub>);

◆□▶ ◆□▶ ◆□▶ ◆□▶ ● □

66 / 91

• when this occurs for the first time we have  $N(\mathcal{M}) \leq c_1 n$ .

### Outline of Probabilistic Algorithm

- randomly select a sample of *m* points,  $S_1 = {\mathbf{x}_{i_1}, ..., \mathbf{x}_{i_m}}$  of the set  $S = {\mathbf{x}_1, ..., \mathbf{x}_n}$ ; find  $\delta(S_1)$ ;
- construct a mesh  $\mathcal{M}$  with mesh size  $\delta_1(S_1)$ ;
- if m = m(n) is appropriately chosen, then with high probability we have N(M) = O(n);
- since  $\delta(S) \leq \delta$ , by a previous lemma, the nearest pair in S will be located in a square of one of the meshes of size  $2\delta$ .

・ロト ・聞 ト ・ 国ト ・ 国ト 二 国

### Success on a Partition

- Let π = {S<sub>1</sub>,..., S<sub>k</sub>} be a partition of S. If t : {1,..., m} → S is an injection, that is, a choice of m elements of S, then t is an (m, π)-success if there is a block S<sub>i</sub> of π that contains at least two elements in the range of t. Otherwise we call t an (m, π)-failure.
  If σ is another partition, σ = {H<sub>1</sub>,..., H<sub>ℓ</sub>} of S, then we say that π dominates σ if for every m, the probability of an (m, π)-success is at least equal to the probability of an (m, σ) success on σ.
- t is an  $(m, \pi)$ -failure if no block of  $\pi$  contains more than one element in the range of t.

- 日本 - 4 日本 - 4 日本 - 4 日本 - 4 日本

#### How Many Failures and Successes?

 $t: \{1, \ldots, m\} \longrightarrow S$  is an  $(m, \pi)$ -failure iff the function  $T: \{1, \ldots, m\} \longrightarrow S/\pi$  given by T(p) = [t(p)] for  $1 \le p \le m$  is an injection. If  $|S/\pi| = k$ , the number of injections T is

$$\begin{cases} \frac{k!}{(k-m)!} & \text{if } m \leq k, \\ 0 & \text{if } k < m \leq n \end{cases}$$

Therefore, the number of  $(m, \pi)$ -successes is

4

$$\begin{cases} \frac{n!}{(n-m)!} - \frac{k!}{(k-m)!} & \text{if } m \leq k, \\ \frac{n!}{(n-m)!} & \text{if } k < m. \end{cases}$$

The probability of an  $(m, \pi)$ -success is

$$P(m,\pi,k,n) = \begin{cases} 1 - \frac{\frac{k!}{(k-m)!}}{\frac{n!}{(n-m)!}} & \text{if } m \leq k, \\ 1 & \text{if } k \leq m, \text{ for } k \end{cases}$$

#### Example

 $\tau = \{S_1, S_2\}$  be a partition of a set  $S = S_1 \cup S_2$  with  $|S_1| = p > 1$  and  $|S_2| = q > 1$ . Claim:  $\tau$  dominates the partition  $\sigma$  of S that consists of a block U with

 $|U| = \ell$  and  $p + q - \ell$  singletons if and only if

$$\ell(\ell-1)\leqslant p(p-1)+q(q-1)$$

# Example (cont'd)

#### We have

$$P(m, \tau, k, n) = \begin{cases} 1 - \frac{\frac{2!}{(2-m)!}}{\frac{n!}{(n-m)!}} & \text{if } m \leq 2, \\ 1 & \text{if } 2 < m \end{cases} = \begin{cases} 1 - \frac{2}{n} & \text{if } m = 1 \\ 1 & \text{if } m \geq 2, \end{cases}$$

and

$$P(m, \sigma, n) = \begin{cases} 1 - \frac{\frac{(p+q-\ell+1)!}{((p+q-\ell+1)-m)!}}{\frac{n!}{(n-m)!}} & \text{if } m \leq p+q-\ell+1, \\ 1 & \text{if } k < p+q-\ell+1. \end{cases}$$

Therefore, we must justify the inequality  $P(m, \tau, n) \ge P(m, \sigma, n)$  only for m = 1 and m = 2.

#### Example

Any partition  $\pi$  of a set of six elements into three two-element sets dominates any partition  $\sigma$  of the same set into a 3-element set and three singletons.

The probability of a success in the first case is

$${\mathcal P}(3,\pi,6) = egin{cases} 1 - rac{rac{3!}{(3-m)!}}{rac{6!}{(6-m)!}} & ext{if } m \leqslant 3, \ 1 & ext{if } 3 < m. \end{cases}$$

In the second case, the probability is

$$P(4, \sigma, 6) = egin{cases} 1 - rac{4!}{(4-m)!} & ext{if } m \leqslant 4, \ 1 & ext{if } 4 < m. \end{cases}$$

Clearly,  $\frac{3!}{(3-m)!} \leq \frac{4!}{(4-m)!}$  if  $m \leq 3$ . For m = 4,  $P(3, \pi, 6) = 1 \geq P(4, \pi, 6)$ , so  $\pi$  dominates  $\sigma$ .
### Example

Any partition  $\pi$  of a set of six elements into two three-element sets dominates any partition  $\sigma$  of the same set into a 4-element set and two singletons.

We have

$$P(2, \pi, 6) = \begin{cases} 1 - \frac{\frac{2!}{(2-m)!}}{\frac{n!}{(n-m)!}} & \text{if } m \leq 2, \\ 1 & \text{if } 2 < m. \end{cases}$$

and

$$P(3, \sigma, 6) = \begin{cases} 1 - \frac{\frac{3!}{(3-m)!}}{\frac{n!}{(n-m)!}} & \text{if } m \leq 3, \\ 1 & \text{if } 3 < m. \end{cases}$$

Since  $\frac{2!}{(2-m)!} \leqslant \frac{3!}{(3-m)!}$  it follows, as before, that  $\pi$  dominates  $\sigma$ .

Exercise: Prove that if  $\pi = \{B_1, B_2\}$  is a partition with  $|B_1| = |B_2| = 4$  of a set S with |S| = 8 and  $\sigma = \{H_1, H_2, H_3, H_4\}$  with  $|H_1| = 5$ ,  $|H_2| = |H_3| = |H_4| = 1$ , then  $\pi$  dominates  $\sigma$ .

# The Sum of Two Partitions

### Definition

Let S, S' be two disjoint sets and let  $\pi = \{B_1, \ldots, B_k\}$  be a partition of Sand  $\sigma = \{H_1, \ldots, H_\ell\}$  be a partition of S'. The sum of  $\pi$  and  $\sigma$  is the partition  $\pi + \sigma$  of  $S \cup S'$  given by

$$\pi + \sigma = \{B_1, \ldots, B_k, H_1, \ldots, H_\ell\}.$$

イロト イポト イヨト イヨト 三日

75/91

Note that  $N(\pi + \pi') = N(\pi) + N(\pi')$ .

Let S, S' be two disjoint sets,  $\pi$  be a partition of S and  $\sigma_1, \sigma_2$  be two partitions of S'. If  $\sigma_1$  dominates  $\sigma_2$ , then  $\pi + \sigma_1$  dominates  $\pi + \sigma_2$ .

# Proof (cont'd): Estimation of a lower bound for $m(\pi_1)$

• if  $p \leq q$ , then the inequality  $p(p-1) + q(q-1) \leq (\ell+1)\ell$  implies  $(p+1)^2 \frac{2p(p-1)}{(p+1)^2} \leq (\ell+1)^2;$ 

since for  $p \ge 5$ , we have

$$\sqrt{\frac{40}{36}} \leqslant \sqrt{\frac{2p(p-1)}{(p+1)^2}} \leqslant \sqrt{2},$$

it follows that  $s(p+1)\leqslant \ell+1$  where  $\sqrt{rac{40}{36}}\leqslant s;$ 

- from  $\sigma_1$  we can obtain a partition  $\sigma_2$  using the same process that allowed us to obtain  $\sigma_1$  from  $\sigma$ ;
- repeating this sufficiently many times (about  $\log_{\sqrt{2}} k$  times, where  $k = |\pi|$  we obtain a partition  $\sigma'$  of S which is dominated by  $\pi$ , and all the blocks of  $\sigma'$  except 1 are singletons.

# Proof (cont'd)

For the constant  $\lambda$  we have

$$\lambda = \frac{5}{6} \left( 1 - \frac{2}{6s} \right) \left( 1 - \frac{2}{6s^2} \right) \cdots$$
 (1)

Since the series  $\frac{2}{6s} + \frac{2}{6s^2} + \cdots$  converges we have  $\lambda > 0$  and  $N(\pi) \leq N(\pi')$ .

Let  $\pi$  be a partition of the set S, |S| = n such that  $n \leq N(\pi)$ . If  $n^{\frac{4}{3}}$  pairwise distinct points are drawn at random from S, then the probability of success, i.e., the probability that two elements will be chosen from the same block of  $\pi$  is at least  $\mu(n) = 1 - 2e^{-cn^{\frac{1}{6}}}$ , where  $c = \sqrt{2\lambda}$  for  $\lambda$  defined in Equality (1).

By Theorem given on slide 79,  $\pi$  dominates a partition  $\sigma = \{H_1, \ldots, H_m\}$ , where  $|H_i| = 1$  for  $2 \le i \le m$  and  $\lambda n \le N(\sigma)$ . Thus, for  $p = |H_1|$ , we have  $2\lambda n \le p(p-1)$  so that  $c\sqrt{n} \le p$  for  $c \approx \sqrt{2\lambda}$ .

• the probability that in one choice from S we miss  $H_1$  is  $1 - \frac{p}{n}$ , so smaller than  $1 - \frac{c}{\sqrt{n}}$ ;

• for  $n^{\frac{2}{3}}$  choices the probability of all missing  $H_1$  is smaller than

$$\left(1-\frac{c}{\sqrt{n}}\right)^{\sqrt{n}\cdot n^{\frac{1}{6}}}\approx e^{-cn^{\frac{1}{6}}};$$

• the probability of success (at least two hits in  $H_1$ ) is greater than  $1 - 2e^{-cn^{\frac{1}{6}}}$ .

There exists a constant  $c_2$  so that if we choose at random  $S_1 = \{\mathbf{x}_{i_1}, \dots, \mathbf{x}_{i_m}\}, m = n^{\frac{2}{3}}, \text{ out of } S = \{\mathbf{x}_1, \dots, \mathbf{x}_n\}$  and draw any mesh  $\mathcal{M}$  of size  $\delta(S_1)$ , then the probability that  $N(\mathcal{M}) \leq c_2 n$  is greater than  $\mu(n)$ , where  $\mu(n)$  was defined in the Theorem given on slide 84.

For the set S consider the mesh  $\mathcal{M}_0$  of size  $\delta_0$  given in the Theorem of slide 65, by which S is partitioned so that  $n \leq \mathcal{N}(\mathcal{M}_0) \leq c_1 n$ . Since  $|S_1| = n^{\frac{2}{3}}$ , the probability that two points of  $S_1$  fall with one square of  $\mathcal{M}_0$  is greater than  $\mu(m)$ .

- there are 16 meshes M<sub>1</sub>,..., M<sub>16</sub> derived from M<sub>0</sub> by quadrupling the mesh size δ<sub>0</sub>; the basic square of each consists of 16 basic squares of M<sub>0</sub>;
- if  $\delta(S_1) \leq \delta_0 \sqrt{2}$ , then for any square mesh with mesh size  $\delta_1$  each of its squares will be a subset of a square of one of the  $\mathcal{M}_i$ ,  $1 \leq i \leq 16$ ; thus,  $N(\mathcal{M}) \leq \sum_{i=1}^{16} N(\mathcal{M}_i)$ ;
- since  $N(\mathcal{M}_0) \leq c_1 n$ , by the Theorem on slide 64,  $N(\mathcal{M}_i) \leq c_1^3 n$  for  $1 \leq i \leq 16$ .

Thus, with probability greater than  $\mu(n)$ ,  $N(\mathcal{M}) \leq 16c_1^3 n$ .

◆□ → ◆聞 → ◆臣 → ◆臣 → □ 臣

For any set S, |S| = n, if  $S_1$  is a subset of S such that  $|S| = n^{\frac{2}{3}}$  is chosen at random and a mesh  $\mathcal{M}$  of size  $\delta(S_1)$  is formed, then the expected value of  $N(\mathcal{M})$  is smaller than  $c_2n$ .

### By the Theorem on slide 86

$$P(S_1 \mid c_2 n \leq N(\mathcal{M})) \leq 1 - mu(n) = 2e^{-cn^{\frac{1}{6}}}$$

Since  $N(\mathcal{M}) \leq n(n-1)$ , the expected contribution from the choices of  $S_1$  for which mesh size  $\delta(S_1)$  leads to a mesh  $\mathcal{M}$  with  $c_2n \leq N(\mathcal{M})$ , is smaller than  $n(n-1)e^{-cn^{\frac{1}{6}}}$ , which tends to 0 when *n* grows. Hence, the expected value of  $N(\mathcal{M})$  is smaller than  $(c_2 + \epsilon)n$  for  $\epsilon > 0$  and *n* sufficiently large.

- The main benefits of random algorithms: simplicity and speed.
- A wide variety of applications.
- Beautiful mathematics!
