Remember how `cond` works:

```
(cond (<condition> <exp> <exp> <exp> ...)  
(elseif <condition> <exp> <exp> <exp> <exp> ...))  
(elseif <condition> <exp> <exp> <exp> <exp> ...)  
...  
(else <exp> <exp> <exp> ...)  
;; this clause is optional
```
(define (count1 x)
  (cond ((= x 0) (display x))
     (else (display x)
                (count1 (- x 1)))))

(define (count2 x)
  (cond ((= x 0) (display x))
     (else (count2 (- x 1))
                (display x) )))
Now evaluate

==> (count1 4)

and

==> (count2 4)
Let’s print them both out:

(count1 4)
(display 4) ;; prints 4
(count1 3)
(display 3) ;; prints 3
(count1 2)
(display 2) ;; prints 2
(count1 1)
(display 1) ;; prints 1
(count1 0)
(display 0) ;; prints 0

so it prints out

43210
()
;; this is the actual value of (count1 4)
(count 4)
(count 3)(display 4)
(count 2)(display 3)(display 4)
(count 1)(display 2)(display 3)(display 4)
(count 0)(display 1)(display 2)(display 3)(display 4)
(display 0)(display 1)(display 2)(display 3)(display 4)

so it prints out

01234

() ;; this is the actual value of (count 4)
Notice the difference in behavior at run-time: `count2` cannot display anything until the end – it has to store up all the display actions until the final `(count2 0)` is evaluated.

What actually happens is that these actions are in effect pushed onto a run-time stack.

`count1`, on the other hand, does not need to defer any operations, and so doesn’t need to push anything on a stack as it executes.
The way you can tell which of these behaviors will happen is to look at the nature of the recursive call in each case:

- In count1, the recursive call to count1 is the last thing that is executed in the body of count1.
- Thus by the time the recursive call is made, all the rest of the body has been executed (or “evaluated”), and there is nothing that needs to be deferred.
- This is called *tail recursion*. It leads to a run-time behavior that does not defer any operations.
- In other languages such behavior is normally written as a loop.
- In Scheme, we tend to write this recursively, but since this is tail recursion, A&S call this kind of code *iterative*.
- We, however, along with everyone else in the world, call it *tail recursion*.
In `count2`, the recursive call to `count2` in the body of `count2` is followed by another expression to evaluate.

Thus, this code is not tail recursive, and the evaluation of that following expression needs to be deferred. This kind of code is called *recursive* by A&S.

So you have to be a bit careful when reading the book: when the authors use the term *recursive*, they do not mean *tail recursive*.
Thus, both `count1` and `count2` are syntactically recursive. But `count1` is tail recursive while `count2` is not.

As we will see again and again, tail recursion is the natural way to represent iterative computations (that is, computations written as loops in other programming languages) in Scheme.

In most computer languages on the other hand, iterative computations must be represented by special iteration constructs like `for` loops in C or `do` loops in Fortran.

But in Scheme, they can be represented by tail-recursive procedures, which (by the Scheme standard) must be implemented as iterations.

We’ll talk a lot more about this as the course goes on.
Newton's Method

- This is the “divide-and-average” method for finding square roots, which is extremely efficient (the number of correct digits approximately doubles with each iteration).
- For example, to find $\sqrt{2}$, we first pick any initial guess, say 1, and proceed as follows:

<table>
<thead>
<tr>
<th>Guess</th>
<th>Quotient</th>
<th>Average</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>$\frac{2}{1} = 2$</td>
<td>$\frac{2 + 1}{2} = 1.5$</td>
</tr>
<tr>
<td>1.5</td>
<td>$\frac{2}{1.5} = 1.33333$</td>
<td>$\frac{1.33333 + 1.5}{2} = 1.4167$</td>
</tr>
<tr>
<td>1.4167</td>
<td>$\frac{2}{1.4167} = 1.4118$</td>
<td>$\frac{1.4118 + 1.4167}{2} = 1.4142$</td>
</tr>
<tr>
<td>1.4142</td>
<td>...</td>
<td>...</td>
</tr>
</tbody>
</table>
(define (sqrt-iter guess x)
  ;; This implements the iteration.
  (if (good-enough? guess x)
      guess
      (sqrt-iter (improve guess x) x) ))

(define (improve guess x)
  (average guess (/ x guess)) )

(define (average x y)
  (/ (+ x y) 2) )
(define (good-enough? guess x)
  ;; guess, x could be a, b (for instance) here
  (< (abs (- (square guess) x)) .001) )
;; .001 is a "magic number"

(define (sqrt x)
  ;; Here’s where we start. We package up
  ;; the data and start the iteration.
  (sqrt-iter 1 x) )
Here is the *call graph* for the square root algorithm we just wrote down:
The book rewrites the Scheme code above like this:

\[(\text{define} \ (\text{sqrt} \ x))\]
\[
(\text{define} \ (\text{good-enough?} \ \text{guess} \ x) \n \quad (\text{<} \ (\text{abs} \ (- \ (\text{square} \ \text{guess}) \ x)) \ .001)) \)
\[
(\text{define} \ (\text{improve} \ \text{guess} \ x) \n \quad (\text{average} \ \text{guess} \ (/ \ x \ \text{guess})) \)
\[
(\text{define} \ (\text{average} \ x \ y) \n \quad (/ \ (+ \ x \ y) \ 2)) \)
\[
(\text{define} \ (\text{sqrt-iter} \ \text{guess} \ x) \n \quad (\text{if} \ (\text{good-enough?} \ \text{guess} \ x) \n \quad \text{guess} \n \quad \quad (\text{sqrt-iter} \ (\text{improve} \ \text{guess} \ x) \ x)) \)
\]
\[(\text{sqrt-iter} \ 1 \ x))\]
All the user cares about is the function $\sqrt{}$.
The internal details can be hidden, as they are here.
Actually, it would be even better to write the code in a way that accurately reflects the call graph, like this:

```
(define (sqrt x)
  (define (sqrt-iter guess x)
    (define (good-enough? guess x)
      (< (abs (- (square guess) x)) .001))
    (define (improve guess x)
      (define (average x y)
        (/ (+ x y) 2))
      (average guess (/ x guess)))
    (if (good-enough? guess x)
        guess
        (sqrt-iter (improve guess x)))) ; end sqrt-iter
  (sqrt-iter 1 guess))
```
Variables get looked up in the innermost scope in which they are found.

This is called *lexical scoping*.

Now we can remove the variables available from an outer scope.

These are all the inner $x$’s *except* the $x$ in average, as well as all the guess’s inside $\text{sqrt-iter}$. 
Lexical Scoping

(define (sqrt x)
  (define (sqrt-iter guess)
    (define (good-enough?)
      (< (abs (- (square guess) x)) .001) )
    (define (improve)
      (define (average x y)
        (/ (+ x y) 2))
      (average guess (/ x guess)))
    (if (good-enough?)
      guess
      (sqrt-iter (improve)))) ; end sqrt-iter
  (sqrt-iter 1))

Note that x was originally $bound$ in improve, but now it is $free$ (its value is not passed in, but is obtained from an outer scope).
Euclid’s algorithm computes the GCD (greatest common divisor) of two numbers $a$ and $b$:

\[
\begin{array}{c|c}
 a & b \\
\hline
 206 & 40 \\
 40 & 6 \\
 6 & 4 \\
 4 & 2 \\
 2 & 0 \\
\end{array}
\]

so the GCD of 206 and 40 is 2.
A second application: the Euclidean algorithm

algorithm in Scheme, using the primitive procedure remainder:

(define (gcd a b)
  (if (= b 0)
    a
    (gcd b (remainder a b)) ))

Theorem (Lamé, 1845)

If Euclid’s algorithm requires $k$ steps, then the smaller of the two input numbers is $\geq$ the $k^{th}$ Fibonacci number.
Lamé’s theorem can be proved by induction.

We start out the algorithm with two numbers \(a\) and \(b\), where \(a > b\).

Let us set out the computation as follows:

\[
\begin{align*}
\text{\(n - 1\) steps} \\
\begin{array}{cccccc}
 n & F_n & a & b \\
 n - 1 & F_{n-1} & b & a \mod b \\
 n - 2 & F_{n-2} & a \mod b & . \\
\end{array}
\end{align*}
\]

\[
\begin{align*}
\begin{array}{cccc}
3 & 2 & x & y \\
2 & 1 & y & z \\
1 & 1 & z & 0 \\
\end{array}
\end{align*}
\]
• Here the number of steps in the process is $k = n - 1$. (That is, there are $n - 1$ steps to get from the top row to the bottom.)
• If $0 < b < a$ (as is true here), then $a - b \geq a \mod b$. 

\[
\begin{align*}
\text{0} & \quad \text{b} & \quad \text{2b} & \quad \text{3b} & \quad \text{4b} & \quad \text{5b} & \quad \text{6b} & \quad \text{7b} & \quad \text{a} & \quad \text{8b} & \quad \text{9b} \\
\text{a - b} & & & \text{a mod b}
\end{align*}
\]
Proof of Lamé’s theorem

This is simply because $a \mod b$ is what is left after you subtract as many $b$’s from $a$ as you can.

Since $b < a$, you can subtract at least 1 $b$, so $a - b \geq a \mod b$.

Thus $a \mod b + b \leq a$.

That is, in the second column from the right, the top element is $\geq$ the sum of the next two elements below it.

By the same reasoning, this property holds all the way down that column. Further, we know that $y$ and $z$ must be $\geq 1$. 
Proof of Lamé’s theorem

Working back up, we see that we can put in $\geq$ signs:

\[
\begin{cases}
  n & F_n \leq a \quad b \\
  n - 1 & F_{n-1} \leq b \quad a \text{ mod } b \\
  n - 2 & F_{n-2} \leq a \text{ mod } b \\
  \vdots & \vdots \\
  3 & 2 \leq x \quad y \\
  2 & 1 \leq y \quad z \\
  1 & 1 \leq z \quad 0
\end{cases}
\]

and so we see that $a \geq F_n$, and $b \geq F_{n-1}$. Since the number of steps in the algorithm is just $k = n - 1$, we have $b \geq F_{n-1} = F_k$, which is what the theorem asserts, and we are done.
Let us consider the factorial function $n! = 1 \cdot 2 \ldots n$. We can compute this in Scheme as follows:

```
(define (factorial n)
  (if (= n 1)
      1
      (* n (factorial (- n 1))))
```

How Does It Work

(factorial 6)
(* 6 (factorial 5))
(* 6 (* 5 (factorial 4)))
(* 6 (* 5 (* 4 (factorial 3))))
(* 6 (* 5 (* 4 (* 3 (factorial 2)))))
(* 6 (* 5 (* 4 (* 3 (* 2 (factorial 1))))))
(* 6 (* 5 (* 4 (* 3 (* 2 1)))))
(* 6 (* 5 (* 4 (* 3 2))))
(* 6 (* 5 (* 4 6))
(* 6 (* 5 24))
(* 6 120)
720
This is an example of what the authors of our text call a *recursive* procedure.

As we explained before, they call it recursive because the operations are deferred.

We keep saving the numbers 6, 5, and so on until the very end, when they get all multiplied together.

But suppose we didn’t really save them – suppose we kept multiplying them as we went on, and passed the partial products on as a parameter to the function?

Then there would be nothing to collect at the end.
(define (factorial n)
  (fact-iter 1 n))

(define (fact-iter product count-down)
  (if (= count-down 1)
      product
      (fact-iter (* product count-down)
                  (- count-down 1)))))
(factorial 6)
(fact-iter 1 6)
(fact-iter 6 5)
(fact-iter 30 4)
(fact-iter 120 3)
(fact-iter 360 2)
(fact-iter 720 1)

720
The book gives a similar version, except that it counts up instead of down.

Note that in this version we need a third argument to fact-iter, because we are comparing count to max-count, rather than to 1.

\[
\text{(define } (\text{factorial } n) \text{)}
\]
\[
(\text{fact-iter } 1 \ 1 \ n) \ )
\]

\[
(\text{define } (\text{fact-iter } \text{ product count max-count}) \text{)}
\]
\[
(\text{if } (> \text{ count max-count)} \text{)}
\]
\[
\text{ product}
\]
\[
(\text{fact-iter } (* \text{ count product})
\]
\[
(+ \text{ count 1})
\]
\[
\text{max-count) )}
\]
(factorial 6)
(fact-iter 1 1 6)
(fact-iter 1 2 6)
(fact-iter 2 3 6)
(fact-iter 6 4 6)
(fact-iter 24 5 6)
(fact-iter 120 6 6)
(fact-iter 720 7 6)
720
So as we saw before with count1, although these versions of the factorial procedure are syntactically recursive, none of the operations are deferred – we don’t accumulate a big list of “things to do”.

In an actual implementation, these “things” would be accumulated on the stack.

For this reason, these new computations are called iterative.

And in fact it is easy to see that the code for both these versions of factorial is tail-recursive.
Exercise

1. Rewrite this last version of factorial so that fact-iter is an internal definition.

2. Show that the third argument to fact-iter can then be eliminated.
Recursion versus iteration: the Fibonacci Numbers

For another example of recursion, let us compute the Fibonacci numbers:

\[
\begin{array}{cccccccccc}
0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & n \\
0 & 1 & 1 & 2 & 3 & 5 & 8 & 13 & 21 & F_n
\end{array}
\]

The recursive (mathematical) definition of these numbers is as follows:

\[
fib(n) = \begin{cases} 
0 & \text{if } n = 0 \\
1 & \text{if } n = 1 \\
fib(n - 1) + fib(n - 2) & \text{otherwise}
\end{cases}
\]
(define (fib n)
    (cond ((= n 0) 0)
          ((= n 1) 1)
          (else (+ (fib (- n 1)) (fib (- n 2))))))
What Could Possibly Go Wrong?

Well, everything...

```
(λx.fib x 0) (fib 1) (fib 1) (fib 0) (fib 1) (fib 0) (fib 2) (fib 2) (fib 0) (fib 1) (fib 2) (fib 1) (fib 0)
```
This kind of process is called *tree recursion* and is extremely inefficient. In fact, the number of leaves in the tree is $F_{n+1}$.

You may know that there is a clever formula for $F_n$:

$$F_n = \frac{1}{\sqrt{5}} \left( \left( \frac{\sqrt{5} + 1}{2} \right)^n - \left( \frac{\sqrt{5} - 1}{2} \right)^n \right)$$

Now $(\sqrt{5} + 1)/2 = 1.618\ldots$, and $\text{abs}(\sqrt{5} - 1)/2 < 1$, so for large $n$,

$$F_n \approx \frac{1}{\sqrt{5}} 1.618^n$$

which is an exponential.

So this recursive method is a perfectly terrible way of computing the Fibonacci numbers. We say that this computation is an $O(1.6^n)$ computation.
On the other hand, there is an iterative way we can perform this computation.

We do this, as before, by saving at each step the results we need to compute the next step:

```scheme
(define (fib n)
  (fib-iter 1 0 n))

(define (fib-iter fn-1 fn-2 count)
  (if (= count 0)
      fn-2
      (fib-iter (+ fn-1 fn-2) fn-1 (- count 1)))))
```
Iterative Fibonacci

Here’s how it works out:

(fib 5)
(fib-iter 1 0 5)
(fib-iter 1 1 4)
(fib-iter 2 1 3)
(fib-iter 3 2 2)
(fib-iter 5 3 1)
(fib-iter 8 5 0)
5

and we see in this case that the computation is $O(n)$, which is a vast improvement.
Suppose we want to compute $b^n$. ($b$ stands for base.)

We will assume that both $b$ and $n$ are non-negative integers.

A naive way to compute this is recursively: we know that $b^n = b \times b^{n-1}$, so we can write...

```
(define (expt b n)
  (if (= n 0)
      1
      (* b (expt b (- n 1)))))
```

This is recursive, because the call to `expt` is deferred in the tail of the computation.

The computation is $O(n)$ in time and $O(n)$ in space.
Recursion Vs. Iteration: Exponentiation

On the other hand, we can compute this iteratively (i.e., using tail-recursion):

\[
\text{(define (expt-iter b counter product)}
\text{  (if (= counter 0)}
\text{    product}
\text{    (expt-iter b}
\text{      (- counter 1)}
\text{      (* b product)))}}
\]

This iterative (i.e., tail-recursive) procedure is $O(n)$ in time, but only $O(1)$ in space.
An even better way to perform this computation is to use a method of successive squaring. We use the fact that

\[
b^n = \begin{cases} 
    \left( b^{n/2} \right)^2 & \text{if } n \text{ is even} \\
    b \cdot b^{n-1} & \text{if } n \text{ is odd}
\end{cases}
\]

(define (fast-expt b n)
    (cond ((= n 0) 1)
          ((even? n) (square (fast-expt b (/ n 2)))))
          (else (* b (fast-expt b (- n 1))))))
This procedure, even though it is not tail-recursive, is $O(\log n)$ in both space and time.

So it’s a little worse in space, but a lot better in time.

**Exercise:** Can you show that this procedure is $O(\log n)$ in time?
